

# Banks, Government Bonds, and Default: What do the Data Say?

Nicola Gennaioli<sup>a</sup>, Alberto Martin<sup>b,\*</sup>, and Stefano Rossi<sup>c</sup>

April 2018

We analyze empirically the holdings of sovereign bonds by over 20,000 banks in 191 countries, and the role of these bonds in 20 sovereign defaults over 1998–2012. We document two robust facts. First, banks hold many government bonds (on average 9% of their assets) in normal times, particularly banks that make fewer loans and operate in less financially-developed countries. Second, within a country and during a default year, bank's holdings of sovereign bonds correlate negatively with subsequent lending. Quantitatively, the average exposure to bonds is associated with a 7 percentage point lower growth rate of loans relative to a bank holding no bonds. This negative correlation is stronger in defaulting countries that are economically and institutionally more developed. These results indicate that the “dangerous embrace” between banks and their government plays a key role in many sovereign defaults around the world, and its strength depends on local conditions.

We are grateful for helpful suggestions from Ricardo Reis (the Editor), several anonymous referees, and from participants at the Columbia conference on Macroeconomic Policy and Safe Assets, the Wharton conference on Liquidity, the Darden International Finance Conference, the NBER Summer Institute Meetings, the Banque de France/Sciences Po/CEPR conference on “The Economics of Sovereign Debt and Default,” the ECGI workshop on Sovereign Debt, the Barcelona GSE Summer Forum, the conference on macroeconomic fragility at the University of Chicago Booth School of Business, and from seminar participants at the University of Illinois at Urbana-Champaign, the Norwegian School of Economics, the Stockholm School of Economics, and HKUST. We also thank Andrea Beltratti, Stijn Claessens, Mariassunta Giannetti, Linda Goldberg, Sebnem Kalemli-Ozcan, Colin Mayer, Camelia Minou, Paolo Pasquariello, Hélène Rey, Sergio Schmukler, Philipp Schnabl, and Michael Weber. Jacopo Ponticelli and Xue Wang provided excellent research assistantship. Gennaioli thanks the European Research Council (grant ERC-GA 241114). Martin acknowledges support from the European Research Council (Consolidator Grant FP7-615651-MacroColl), the Spanish Ministry of Science and Innovation (grant Ramon y Cajal RYC-2009-04624), the Spanish Ministry of Economy and Competitiveness (grant ECO2011-23192), the Generalitat de Catalunya-AGAUR (grant 2009SGR1157), the Ramón Areces Grant and the IMF Research Fellowship.

1    **1. Introduction**

2    Recent theory shows that when banks hold large amounts of sovereign bonds, sovereign default  
3    may hurt their balance sheets, causing a decrease in lending, a banking crisis, and thus an  
4    economic collapse (e.g., Gennaioli, Martin, and Rossi 2014). This mechanism was center stage  
5    during the recent European crisis. Systematic evidence of it, however, is scant. This paper aims  
6    to fill this gap by documenting basic facts from many default episodes around the world.

7           Existing bank level evidence on the “dangerous embrace” between banks and  
8    governments faces two main limitations.<sup>1</sup> First, it focuses on the European debt crisis (e.g., Popov  
9    and Van Horen 2014, De Marco 2016, Battistini, Pagano, and Simonelli 2015), which limits its  
10   scope. It would be useful to know how this mechanism works around the world, including in  
11   poor and emerging economies, which account for the lion’s share of default episodes. Second,  
12   existing work does not analyze how banks become exposed to their government in the first place.  
13   Acharya and Steffen (2014) and Drechsler et al. (2014) stress banks’ excessive risk taking in  
14   government bonds during the European crisis. It remains to be seen how general this channel is  
15   when compared to banks’ demand for government bonds in normal times.

16           To address these issues, we analyze how bank holdings of government bonds shape the  
17   sovereign default-banking crisis nexus in many countries, time periods, and crises. We use the  
18   BANKSCOPE dataset, which has the advantage – relative to the European Stress tests – of

---

<sup>1</sup> Gennaioli et al. (2014) show that countries where banks hold more domestic public bonds exhibit a sharper reduction in aggregate lending during government default. Arteta and Hale (2008) show that defaults are followed by a drop in foreign credit to domestic firms. Borensztein and Panizza (2008) show that defaults are followed by larger GDP contractions when they occur with banking crises. Baskaya and Kalemli-Ozcan (2014) offer evidence from Turkey. Becker and Ivashina (2014) find that public bond purchases by European banks crowd-out corporate lending.

1 reporting the holdings of government bonds (alternatively, “bondholdings” or “bonds”) and  
2 characteristics of over 20,000 banks in 191 countries between 1998 and 2012. Crucially, our  
3 dataset covers 20 sovereign default episodes, 19 of which occurred in emerging markets.<sup>2</sup>

4 Despite its richness, our data does not allow us to identify causal patterns. Instead, our  
5 goal is to unveil robust stylized facts on the cross-country patterns of sovereign crises that can  
6 inform future theoretical work. Our analysis delves around two questions:

7 i. Which banks, and in which countries, hold government bonds? Do banks hold bonds all  
8 of the time, or do they mostly buy bonds in the run-up to and during sovereign defaults?  
9 ii. Do the banks that hold more government bonds exhibit a larger decrease in lending when  
10 their government defaults?

11 We address these questions by running a large battery of tests. In particular, we control  
12 in our regressions for many aggregate economic shocks, for differential exposure of banks to such  
13 shocks, and for a host of bank characteristics. We document two robust facts:

14 1. There is a negative and statistically significant correlation between a bank’s holdings of  
15 domestic government bonds during a sovereign default and its ratio of loans to assets.  
16 This result holds within the same defaulting country and default year. A bank holding the  
17 average amount of bonds reduces its loans-to-assets ratio by about one extra percentage

---

<sup>2</sup> One shortcoming of BANKSCOPE is that it reports a bank’s aggregate public bond exposure, without separating domestic from foreign sovereign bonds. To assess the severity of this problem, we focus on a subsample of banks where we perfectly observe the nationality of banks’ bondholdings and we thoroughly compare it with our BANKSCOPE data. The exercise confirms the presumption of strong home bias in sovereign exposures, indicating that – while imperfect – the BANKSCOPE measure is a good proxy for a bank’s exposure to its domestic government.

points relative to a bank holding zero bonds. In addition, for a given loans-to-assets ratio, the bank holding bonds exhibits lower asset growth during default. As a result, in default years the average exposure to government bonds is associated with a roughly 7 percentage point lower growth rate of loans relative to a bank holding no bonds.

2. During normal times, banks' holdings of government bonds are large (around 9% of assets), particularly for banks that make fewer loans and are located in less financially developed countries. During default episodes, bondholdings go up only slightly and their increase is concentrated in larger (and more profitable) banks. Government bonds held ahead of crises have a strong predictive power for the reduction in bank lending.

Although these findings cannot fully address causality, they do shed light on the two main hypothesis behind the sovereign default-banking crisis nexus. The "demand channel" hypothesis holds that it is other adverse shocks that occur jointly with default (recessions, devaluations, etc.), rather than default per se, which reduce the demand for credit and thus bank lending. The alternative "supply channel" hypothesis holds instead that defaults directly hinder bank lending by damaging the balance sheets of banks that hold government bonds.<sup>3</sup>

Fact 1 above is already suggestive of a supply channel at play because it implies that a bank's bondholdings predicts its decline in lending during sovereign defaults, conditional on any aggregate shock. If the decline in lending was *only* caused by adverse demand shocks, there

---

<sup>3</sup> This channel relies on the assumption of 'imperfect discrimination' (Broner, Martin, and Ventura 2010; Broner and Ventura 2011), whereby governments cannot spare domestic creditors when defaulting on foreign ones. Conventional models of sovereign default assume perfect discrimination instead (e.g., Eaton and Gersovitz 1981).

1 would be no particular reason for it to be stronger among banks holding more government  
2 bonds.

3 Perhaps banks highly exposed to their government expect or happen to face low credit  
4 demand during defaults, for instance because they are more pro-cyclical. However, we find that  
5 the lending policy of highly exposed banks is not disproportionately sensitive to recessions or  
6 devaluations. Hence, differential sensitivity to major shocks is unlikely to account for our results.  
7 In addition, our results are robust to controlling for bank characteristics and their interaction with  
8 default. Finally, we also document that bonds held well before sovereign defaults strongly predict  
9 the post-default decline in credit, which is also consistent with the supply channel. Arguably, pre-  
10 crisis bonds are held for reasons that have little to do with the crisis itself.

11 Together with Fact 2, this last finding sheds new light on the origins of the sovereign  
12 default-banking crisis nexus. Because banks' sovereign exposure is mostly built well before  
13 defaults, the "dangerous embrace" in our data seems largely due to banks' demand for bonds in  
14 normal times. This is not to say that the risk-taking channel, much discussed in the European  
15 context, is not a contributing factor. Rather, our data indicates that this is not an essential or even  
16 an important part of the story in emerging markets.

17 The cross country nature of our data also allows us to document important country level  
18 differences in the unfolding of sovereign crises. We find that the negative association between  
19 bank bondholdings and lending tends to be stronger in defaulting countries that have a fixed  
20 exchange rate regime, that are more economically developed, and that have stronger political  
21 and financial institutions. These findings are obtained by comparing countries with low versus

1 medium scores of institutions and development, because there are very few defaults among  
2 countries with highest scores (perhaps precisely because the cost of default is too large there).

3 The paper proceeds as follows. Section 2 describes the data. Section 3 studies the basic  
4 correlation between bank bondholdings and loans during default (subsection 3.1) and the  
5 demand for public bonds by banks (subsection 3.2). Section 4 concludes.

6 **2. Data**

7 We build a dataset that includes banks' holdings of public bonds and lending activity at the bank-  
8 year level, as well as a large set of bank-level characteristics and macroeconomic indicators that  
9 capture the state of a country's economy.

10 *2.1 BANKSCOPE Accounting Data*

11 We obtain all the bank-level accounting data from the BANKSCOPE dataset, which contains  
12 information on the holdings of government bonds for 20,337 banks in 191 countries between  
13 1998 and 2012 (99,328 bank-year observations). This dataset, which is provided by Bureau van  
14 Dijk Electronic Publishing (BvD), contains balance sheet information on a broad range of bank  
15 characteristics: bondholdings, size, leverage, risk taking, profitability, amount of loans  
16 outstanding, balances with the Central Bank, and other interbank balances. The nationality of the  
17 bonds is not reported, an issue to which we return below. The information in BANKSCOPE is  
18 suitable for international comparisons because BvD harmonizes the data.

1           All items are reported at book value, including bonds.<sup>4</sup> Arguably, since they play a key role  
2       in bank regulation, book-value estimates influence banks' lending decisions. Indeed, as we will  
3       see, the book value of bonds does appear to matter for lending. One important implication of  
4       book-value accounting is that – to a large extent – variations in the bonds-to-assets ratio capture  
5       variations in the relative quantity, as opposed to the market price, of bonds held by banks.<sup>5</sup>

6           We construct our dataset by assembling all annual updates of the unconsolidated  
7       accounts of banks in BANKSCOPE. We filter out duplicate records, banks with negative values of  
8       all types of assets, banks with total assets smaller than \$100,000, and years prior to 1997 when  
9       coverage is less systematic. This procedure yields 99,328 observations of bondholdings at the  
10      bank-year level over 1998-2012. We impose two additional requirements on the remaining  
11      banks. First, each bank must have at least two consecutive years of data, so that we can examine  
12      changes in lending. Second, each bank must have data on the other main variables: leverage,  
13      profitability, cash and short term securities, exposure to the Central Bank, and interbank  
14      balances. The constant-continuing sample for our regressions includes 7,391 banks in 160  
15      countries for a total 36,449 bank-year observations. We take the location of banks to be the one  
16      of its headquarters, as reported in BANKSCOPE. Commercial banks account for 33.2% of our  
17      sample; cooperative banks for 38.2%; savings banks for 20.6%; investment banks for 1.6%; the  
18      rest includes holdings, real estate banks, and other credit institutions.

---

<sup>4</sup> Even in developed economies, banks hold a large fraction of their government bonds in the banking book (which reports book values) rather than in their trading book (which is marked to market). Acharya, Drechsler, and Schnabl (2014) report that EU banks hold on average 85% of their bonds in their banking book.

<sup>5</sup> Book and market value are close to one another during normal times, when bond prices are close to parity. The online appendix shows that our book-value measure approximates fairly well banks' exposure to government bonds at market value and that, if anything, it underestimates in many cases the exposure computed at market values.

1    2.2 *Bondholdings Data*

2    Because BANKSCOPE does not break down bonds by nationality, we now check whether the

3    BANKSCOPE measure of government bonds is a good enough proxy for domestic bonds. To be

4    sure, home bias – the tendency of investors to prefer domestic securities – is widespread in

5    international financial markets (see Karolyi and Stulz 2003 for a survey), so it is reasonable to

6    conjecture that there is home bias in banks' sovereign exposures as well. To assess whether this

7    is the case, we compare our data with other sources that report the nationality of bonds: the

8    country-level measure of "banks' net claims on the government" from the IMF, the bank-level

9    data from the European Stress Tests of 2010-2012 for the subsample of EU banks, and proprietary

10   data from the Central Bank of Argentina for the subsample of Argentine banks during 1997-2004.

[Figure 1 here]

Figure 1 plots averages by country-year of bank bondholdings as a share of total bank assets from BANKSCOPE and from the IMF measure of “financial institutions’ net claims to the government,” also computed as a share of total assets.<sup>6</sup> The mean of the IMF measure is very close to the BANKSCOPE data throughout the sample. The difference between both measures is quite small, less than 0.5% of assets in more than half of the sample. The BANKSCOPE measure is either equal or slightly larger than the IMF one in most of the years, as can be expected given that it includes also foreign bondholdings.<sup>7</sup>

<sup>6</sup> This variable reports commercial banks' holdings of securities plus direct lending minus government deposits. An equivalent measure has been used by Gennaioli, Martin, and Rossi (2014) and by Kumhof and Tanner (2008).

<sup>7</sup> Exceptions are 1999, 2000 and 2002 where the IMF measure overshoots the BANKSCOPE one by 1-1.7% of assets, which is probably due to the fact that the former includes direct lending.

1 Country level IMF data can give us a sense of the reliability of the BANKSCOPE measure of  
2 bonds at the country level, but not at the bank level. We therefore consider two alternative  
3 sources of bank -level data: the EU stress tests of 2010, 2011, and 2012, and proprietary data  
4 from the Argentina's Central Bank during 1997-2004.

[Table I here]

6 Table I reports the mean and the median of the bonds-to-assets ratio according to  
7 BANKSCOPE and to these alternative data sources. It also reports the bank-level correlations  
8 between the ratios reported in these different datasets.

The European stress test data is reassuring. Mean bondholding as a share of assets in the  
stress test (5.12%) is fairly close to the BANKSCOPE measure (8.16%), suggesting that domestic  
bonds capture the bulk of sovereign exposure. This is also true for GIIPS banks, for which the  
stress test reports mean bondholdings of 6.22% against 9.43% of BANKSCOPE. The bank-by-bank  
correlation between the BANKSCOPE and stress test measures is sizeable (0.69 overall and 0.76  
for GIIPS banks). Consider next the data on Argentine banks. Around the Argentine crisis and  
default (1997-2004), Argentine banks held 11.34% of their assets in domestic bonds, while  
BANKSCOPE reports bondholdings of 14.49% of assets.<sup>8</sup> The bank-level correlation is higher than  
that of the EU Stress Test (0.77), moreover, which again confirms the validity of our BANKSCOPE  
measure. Insofar as noise in the BANKSCOPE measure represents classical measurement error, it  
should bias our empirical analysis against finding any results. In the case of Argentina, we can

<sup>8</sup> Importantly, our Argentine data clearly distinguishes between bondholdings held by banks “on their own” and new bond issues, which were used to compensate banks in the aftermath of the 2001 Argentine default. We use exclusively the former measure in our analysis, which if anything biases our results against us.

1 precisely quantify even non-classical measurement error, which also appears to dampen our  
2 results, at least in the sub-sample of Argentine banks.<sup>9</sup>

3 The comparison of the BANKSCOPE data with both IMF country-level data and with the  
4 bank-level data of the EU Stress Tests and the Central Bank of Argentina confirms the  
5 presumption of a strong home bias in banks' bondholdings, and it also indicates that the  
6 BANKSCOPE measure is strongly and significantly correlated with domestic government  
7 exposure. As such, we believe the BANKSCOPE measure is a valid proxy for domestic  
8 bondholdings and we use it in our analysis.

9 [Table II here]

10 Panel A of Table II reports descriptive statistics on these bondholdings around the world.  
11 In non-defaulting countries banks hold on average 9% of their assets in government bonds.  
12 Among countries that default at least once in our sample, this average is 13.5% in non-default  
13 years, and increases slightly to 14.5% of bank assets during default years.

#### 14 2.3 Summary Statistics

15 We consider the distribution of bank characteristics in BANKSCOPE, focusing on: (i) bank size as  
16 measured by total assets, (ii) non-cash assets (i.e. assets other than cash and other liquid  
17 securities), (iii) leverage as measured by one minus shareholders' equity as a share of assets, (iv)

---

<sup>9</sup> To quantify the role of non-classical measurement error, write our bondholdings measure as  $b = b^* + \delta$ , where  $b^*$  is true bonds and  $\delta$  is measurement error. Denote by  $\Delta l$  the change in lending during a given year of default. Measurement error is classical when  $Cov(\Delta l, \delta) = Cov(b^*, \delta) = 0$ . In the Argentine default (2001-2004, 223 bank year obs.) measurement error is not purely classical as  $Cov(\Delta l, \delta) = 0.001781$  and  $Cov(b^*, \delta) = 0.001669$ . In Section 3 we quantify the direction and the magnitude of the estimation distortions for the Argentine sub-sample.

1 loans outstanding as a share of assets, (v) profitability as measured by operating income over  
2 assets, (vi) exposure to the Central Bank as measured by deposits in the Central Bank over assets,  
3 (vii) balances in the interbank market, and (viii) government ownership, a dummy that equals  
4 one if the government owns more than 50% of the bank's equity. To neutralize the impact of  
5 outliers, all variables are winsorized at the 1<sup>st</sup> and 99<sup>th</sup> percentile. Panel B of Table II provides  
6 descriptive statistics for these variables in our sample.<sup>10</sup> Table AI in the online appendix reports  
7 the correlations between different bank characteristics in our sample.

8 **[Table III here]**

9 *2.4 Sovereign Default and Macroeconomic Conditions*

10 We proxy for sovereign defaults with a dummy variable based on Standard & Poor's, which  
11 defines default as the failure of a government to meet a principal or interest payment on the due  
12 date (or within the specified grace period) contained in the original terms of the debt issue.  
13 According to this definition, our sample contains 20 defaults in 17 countries.

14 In our robustness tests, we complement our analysis by using two alternative measures  
15 of sovereign defaults, namely: (i) a monetary measure of creditors' losses given default, i.e.,  
16 "haircuts", from the work of Cruces and Trebesch (2013) and Zettelmeyer, Trebesch, and Gulati  
17 (2012), and; (ii) a market-based measure, whereby a country is defined to be in default either if  
18 satisfies the S&P definition or if its sovereign bond spreads relative to the U.S. or German bonds  
19 exceed a given threshold (following the methodology of Pescatori and Sy 2007).

---

<sup>10</sup> Panel C of Table II shows the characteristics of banks involved in the stress test. These banks are larger and extend more loans than the median BANKSCOPE bank. Leverage and cash are instead similar to the BANKSCOPE ones.

- 1 Table AII of the online appendix reports the defaults in our constant-continuing sample.
- 2 There is a large variation in the size of defaulting countries and in the extent of bank coverage.
- 3 To avoid picking up idiosyncratic features of default in countries that are small and have few
- 4 banks, we show that our results are very similar across many subsamples.<sup>11</sup>

5 Data on the macroeconomic conditions of the different countries is obtained from the  
6 IMF's International Financial Statistics (IFS) and the World Bank's World Development Indicators  
7 (WDI). Table AIII in the online appendix describes all variables. To measure the size of financial  
8 markets we use the ratio of private credit provided by money deposit banks and other financial  
9 institutions to GDP, which is drawn from Beck et al. (2000). This widely used measure is an  
10 objective, continuous proxy for the size of the domestic credit markets.

## 11     *2.5 Sovereign Bond Returns*

12 Realized sovereign bond returns are obtained from the J.P. Morgan's Emerging Market Bond  
13 Index Plus file (EMBIG+) and from the J.P. Morgan's Global Bond Index (GBI) file (see Kim (2010)  
14 for a detailed description; see also Levy-Yeyati, Martinez-Peria, and Schmukler (2010)).<sup>12</sup> Figure  
15 2 plots sovereign bond prices around default for the subsample of defaulting countries. It shows  
16 that bond prices drop very fast, just two-three months prior to the day of the default.

17 [Figure 2 here]

<sup>11</sup> One concern here is that some small countries with few banks may drive our results (in eight defaulting countries our data covers five banks or less.). The second is that our results may only hold in large countries like Argentina and Russia. Our extensive robustness exercises show that our results do not depend on these particularities.

<sup>12</sup> These indices aggregate the realized dollar returns of sovereign bonds of different maturities and denominations, assuming that coupons or pay downs are reinvested. This data is available for 68 countries in our sample and it covers 7 default episodes in 6 countries (Argentina, Russia Greece, Cote d'Ivoire, Ecuador, and Nigeria). Thus, using bond returns reduces sample size. Table AIV in the online appendix contains descriptive statistics on bond returns.

1 This J.P. Morgan data allows to construct proxies for expected returns, which are not directly  
2 observable. We follow a standard two-step process. In the first step, bond returns are regressed  
3 on a set of country-specific economic, financial, and political risk factors:

4

$$R_{c,t} = \gamma_t + \beta_0 + \beta_1 Z_{c,t-1} + u_{i,c,t}, \quad (1)$$

5 where  $R_{c,t}$  is the realized return of government bonds in country  $c$  at time  $t$ ,  $\gamma_t$  are time dummies  
6 (capturing variations in the global risk-free rate), and  $Z_{c,t-1}$  is a vector of political, economic and  
7 financial risk ratings compiled by the International Country Risk Guide (see Comelli (2012) for a  
8 similar method). In the second stage, expected returns are measured as the fitted values of this  
9 first-stage regression. Table AV in the online appendix reports the results of the first-stage  
10 estimation of Equation (1). There is a strong negative correlation between the risk ratings at time  
11  $t$  and realized returns at time  $t + 1$ . Because these ratings are decreasing in risk, this result is  
12 consistent with theory: higher bond returns compensate investors for higher risk.

13 **3. Estimation Results**

14 This section presents our regression results. Section 3.1 reports results on the relationship  
15 between sovereign defaults, bondholdings and loans. Section 3.2 analyzes banks' demand for  
16 bonds, in particular the extent to which these are purchased in normal times or in default years.

17 *3.1 Defaults, Bondholdings and Loans*

18 As a first step, we use our data to assess the correlation between a bank's bondholdings and its  
19 lending during default events. Let  $\Lambda_{i,c,t}$  denote the change in the loans-to-assets ratio of bank  $i$ ,

1 in country  $c$ , between years  $t - 1$  and  $t$ , and; let  $B_{i,c,t-1}$  denote the bonds to assets ratio of bank  
2  $i$ , in country  $c$ , in year  $t - 1$ . Our most basic test consists in running the regression:

3 
$$\Lambda_{i,c,t} = \gamma_0 + \gamma_1 \cdot B_{i,c,t-1} + \gamma_2 \cdot Def_{c,t-1} + \gamma_3 \cdot Def_{c,t-1} \cdot B_{i,c,t-1} + \gamma_4 \cdot L_{i,c,t-1}$$
  
4 
$$+ \gamma_5 \cdot Def_{c,t-1} \cdot L_{i,c,t-1} + \mu_{i,c,t}, \quad (2)$$

5 where  $Def_{c,t-1}$  is a dummy variable taking value 1 if country  $c$  is in default at  $t - 1$  and value 0  
6 otherwise, and  $L_{i,c,t-1}$  is the bank's loan-to-asset ratio that controls for the initial level of lending.  
7 This specification offers our minimal benchmark for quantification. We also run versions of  
8 Equation (3) that include country dummies, time dummies, and their interaction, as well as a  
9 large set of bank characteristics (alone and interacted with default) to control for banks'  
10 potentially different business models. Standard errors are clustered at the bank level throughout  
11 (clustering errors at the country level yields very similar results).

12 The coefficient of interest is  $\gamma_3$ . A negative value of  $\gamma_3$  indicates that, ceteris paribus,  
13 banks holding more sovereign bonds extend fewer loans during sovereign defaults. Table IV  
14 reports our estimates. Column (1) reports our baseline estimate of Equation (3). The estimate  
15 for  $\gamma_3$  is negative and significant, indicating that a bank's holdings of sovereign bonds are  
16 negatively associated with its lending during sovereign defaults.

17 **[Table III here]**

18 The results do not change when we introduce time dummies in column (2) and country  
19 dummies in column (3). Column (4) presents a more stringent test, which includes in our  
20 regressions also the interaction of country and time dummies. By doing so, we effectively control

1 for *any* country specific shocks such as recessions, exchange rate devaluations, etc., that may  
 2 cause both a government default and a drop in the demand for credit. The inclusion of  
 3 country\*time dummies more than doubles the R-squared. Consistent with intuition, country-  
 4 specific time-varying shocks are important determinants of bank lending. At the same time, our  
 5 main coefficient remains robust. Within *the same* defaulting country-year, it is the banks most  
 6 loaded with government bonds that reduce their lending the most. This is confirmed in column  
 7 (5) when we control for a large set of bank level characteristics.<sup>13</sup>

8 One remaining concern is that, within the same country-year, banks holding more  
 9 government bonds may happen to have greater exposure to the country-level, time-varying  
 10 macroeconomic shocks. For instance, these banks may be unhedged against macroeconomic  
 11 shocks like currency devaluations, so their lending might drop because of the devaluation and  
 12 not because of the bonds they hold. To assess this possibility, Table IV includes in the regressions  
 13 of column (5) of Table III the interaction between bank bondholdings and two major  
 14 macroeconomic factors: a country's GDP growth and its exchange rate devaluation relative to  
 15 the U.S. dollar. The interaction between bank bondholdings and sovereign default remains  
 16 negative, statistically significant, and its magnitude is stable. The R-squared in all columns is very

---

<sup>13</sup> We can quantify non-classical measurement error for the Argentine default (2001-2004, 223 bank-year obs.). As before, write bondholdings as  $b = b^* + \delta$ , where  $b^*$  is true bonds and  $\delta$  is measurement error. Denote by  $\Delta l_t$  the change in lending from  $t-1$  to  $t$  during default. By regressing  $\Delta l_t$  on  $b_{t-1}$  and  $l_{t-1}$ , the coefficient  $\beta$  of  $b_{t-1}$ , is:

$$\beta = \beta^* \frac{\text{var}(l_{t-1})\text{var}(b_{t-1}^*) - \text{cov}(b_{t-1}^*, l_{t-1})^2}{\text{var}(l_{t-1})\text{var}(b_{t-1}) - \text{cov}(b_{t-1}, l_{t-1})^2} + \frac{\text{var}(l_{t-1})\text{cov}(\Delta l_t, \delta_{t-1}) - \text{cov}(l_{t-1}, \delta_{t-1})\text{cov}(\Delta l_t, l_{t-1})}{\text{var}(l_{t-1})\text{var}(b_{t-1}) - \text{cov}(b_{t-1}, l_{t-1})^2} \quad (3)$$

where  $\beta^*$  is the true coefficient. In the sub-sample of Argentine banks during the 2001-2004 default, the coefficient estimated with Bankscope data is  $\beta = -0.152$ , while the coefficient estimated using the "true" bondholdings measure of the Central Bank Argentina is  $\beta^* = -0.774$ . Intuitively, in the Argentine data the effect of classical measurement dominates and it results in a significant downward bias of our estimate.

1 close to that of column (5) of Table III. Of the two macroeconomic shocks, only GDP growth has  
2 a significant (positive) effect on lending by banks holding more bonds.

3 **[Table IV here]**

4 We perform further robustness checks by considering different subsamples and  
5 definitions of default. Table V reports this analysis. Columns (1) and (2) show that our results are  
6 unchanged if we exclude government owned banks from our sample, for the behavior of these  
7 banks may be distorted by politics. We show that our results are not driven by “unimportant”  
8 defaults or by defaulting countries with just a few banks by excluding the smaller defaulting  
9 countries in our sample, both as measured by GDP per capita, and by the size of default (columns  
10 3 and 4). We also exclude defaulting countries with fewer than 5, 10, and 15 banks, respectively  
11 (columns 5-10). The results are robust and point estimates are stable, suggesting that our results  
12 are unlikely to be driven by severe omitted variables or special subsamples. Our results survive  
13 under alternative definitions of defaults such as: (i) the haircut measure of default constructed  
14 by Cruces and Trebesch (2013) and Zettelmeyer et al. (2012), which measures the severity of a  
15 default (columns 11 and 12), and; (ii) the augmented measure that adds to the S&P default  
16 dummy also events in which sovereign spreads exceed 1,000 basis points (columns 13 and 14).<sup>14</sup>

17 **[Table V here]**

---

<sup>14</sup> The paucity of data on spreads limits this exercise to the larger, economically more important defaults. The additional defaults examined here are Ireland in 2011, Portugal 2011 and 2012, Greece in 2011, and Ukraine in 2001.

1 We also consider alternative measures of bank lending. Because changes in the loans-to-  
2 assets ratio may reflect changes in total assets, our previous results may pick up deleveraging.  
3 We thus estimate two alternatives to Equation (3), where the dependent variable is, respectively:

4 
$$\left( \frac{L_{i,c,t} - L_{i,c,t-1}}{A_{i,c,t-1}} \right) \text{ and } \Delta \log(L_{i,c,t}), \quad (4)$$

5 i.e., the change in loans divided by lagged assets and the growth rate of loans. All right-hand side  
6 variables are the same as in specification (3). Kashyap and Stein (2000) use a similar specification.  
7 We present the results from these alternative specifications in Panels A and B of Table AVI in the  
8 online appendix, respectively. Our results are confirmed. If anything, they become stronger.

9 In sum, consistent with the supply channel hypothesis, a bank's holding of sovereign  
10 bonds is robustly associated with a decline in its lending during sovereign defaults. Our results  
11 are quantitatively large. Consider the following back-of-the-envelope calculation based on our  
12 baseline specification in column (1) of Table III: relative to a bank that holds no public bonds, a  
13 bank with the average bonds-to-assets ratio of 14.49% experiences an additional fall in the loans-  
14 to-assets ratio of one percentage point. For a given growth rate of assets, this implies a bank with  
15 average bondholdings experiences a 2 percentage points lower lending growth relative to banks  
16 with no bonds. But since the assets of banks with average bondholdings also grow less than those  
17 of banks that hold no bonds during default years, our estimates imply that banks with average  
18 bondholdings experience an overall 7 percentage points lower lending growth.<sup>15</sup>

---

<sup>15</sup>To see the logic of the quantification, note that in column (1) of Table III the drop in the loans to assets ratio for a bank holding the average amount of bonds relative to a bank holding no bonds is  $(0.038 - 0.1) * (0.145) = -0.009$  (where 0.145 are the bonds held by the average bank in default). This effect alone corresponds to a lower growth

Having established that our baseline results are robust and large, we now exploit the cross-country dimension of our data to examine how they depend on key country-characteristics, like the type of exchange rate regime, the level of development, and the quality of financial, economic and legal institutions. To assess the role of the exchange rate regime, Equation (3) is separately estimated in countries that have a hard exchange-rate peg, a soft exchange-rate peg, and no peg, according to the classification proposed by Shambaugh (2004).<sup>16</sup> To assess the role of economic development, Equation (3) is separately estimated in subsamples of countries with high (\$35K per year, measured in 2010 USD), middle (between \$7K and \$35K), and low (below \$7K) average per capita income. To assess the role of financial institutions—as measured by the Djankov et al.’s (2007) creditor rights score, which ranges between 0 (lowest) and 4 (highest)—Equation (3) is separately estimated in subsamples of countries that exhibit on average a high (an average score above 2), medium (an average score of 2), or low (an average score below 2) score on this index. To assess the role of economic and political institutions we use the ICRG (2013) scores of economic and political risk, which range from 0 to 50 (lowest economic risk) and 100 (lowest political risk), respectively. For each type of risk, we split the sample in three sub-samples of countries, with high (score above 40 or 80, respectively), medium or low (score below 35 or 65, respectively) institutional quality.<sup>17</sup>

---

rate of loans of  $0.009 * \left(\frac{A_t}{L_{t-1}}\right) = 0.009 * 2.2 = 0.02$ . Then, because exposed banks exhibit—for a given loans to asset ratio—a 5 percentage points lower growth rate of assets during default, their growth rate of loans is 2+5=7 percentage points lower. These estimates line up well with those in Table AVI, where we find that in default years total lending of banks holding average bonds grows by 5.5 percentage points less than that of banks with no bonds.

<sup>16</sup> In our defaulting countries the exchange rate regime is stable in the years before, during and after default.

<sup>17</sup> These subsamples were designed to have a roughly equal number of observations in the middle and bottom group. The top category of developed economies is the largest group, as it contains between 60% and 66% of all observations. These countries are in a separate category because there is virtually no default there. Two exceptions are Kenya and Nigeria in the creditor rights split: they both default and attain a maximum score of 4. On the other

1 Table VI below reports, for each policy or institutional variable, the coefficient  $\gamma_3$  of the  
2 default-bondholdings interaction estimated within each of the three groups of countries. Once  
3 again, these exercises cannot provide causal identification but offer stylized facts that  
4 quantitative theories may seek to target.

[Table VI here]

6 The association between post-default decline in lending and bank bondholdings appears  
7 to be stronger in countries that have pegged exchange rates relative to countries that have a soft  
8 peg or no peg at all. Regarding economic, financial, and political variables, this association also  
9 tends to be stronger in countries with medium (as opposed to low) economic and institutional  
10 development, as measured through all our indicators except for creditor rights (where the  
11 difference between groups is not significant). This is consistent with the notion that in these  
12 middle income countries financial intermediation may play a larger economic role, making these  
13 countries more vulnerable to disruption by sovereign crises, consistent with the mechanism  
14 explored in Gennaioli, Martin and Rossi (2014).

To conclude, we wish to note that our findings on the association between bank lending and bondholdings could be due to both the bonds bought by a bank well before a sovereign default and those potentially bought in the run-up to the crisis and during the crisis itself. The latter “risk-taking during the crisis” mechanism has been emphasized during the recent European crisis. To assess this possibility, we run modified versions of Equation (3), in which we replace

hand, the medium and low sub-samples in which most sovereign defaults occur roughly correspond to middle income versus poor countries. These two groups have similar numbers of bank-year observations.

1 our measure of a bank's bondholdings  $B_{i,c,t-1}$  with alternative measures that reflect the bonds  
2 held by the bank in normal times, before default occurs.

3 We first run a cross sectional version of Equation (3) in which we regress the change in a  
4 bank's loans to assets ratio occurring during the first two years of default on its bondholdings in  
5 the year *before* default. The regression includes country and year dummies. Estimation results  
6 are reported in column (1) of Table VII. Bonds held in the year before default have a negative  
7 association with changes in lending during the first two years of the default episode. The point  
8 estimate is slightly more than twice as large as the one obtained in Table IV, so that – on a per-  
9 year basis – the result is close to the upper bound of our previous estimates.

10 [Table VII here]

11 One concern with the specification of column (1) is that a bank's holdings of sovereign  
12 bonds in the year prior to default may already reflect an increase in sovereign risk. This seems  
13 unlikely, given that – as shown by Figure 2 – bond returns spike in close proximity to the moment  
14 of default. In any event, column (2) addresses this concern by using a more conservative proxy  
15 of normal-times bonds: the average holdings in the three years prior to the onset of default. The  
16 previous results are confirmed.<sup>18</sup>

17 In sum, there is a strong and negative correlation between a bank's bondholdings at the  
18 time of default and its subsequent lending. Although this evidence is strongly consistent with the  
19 supply channel, it falls short of perfectly identifying it. First, although we control for all aggregate

---

<sup>18</sup> As these tests require consecutive bank data for a five-year window around a default, they effectively focus on large banks in large defaulting countries such as for example Argentina, Greece, and Ecuador.

1 shocks, our bank-level data does not allow us to control for all heterogeneity among banks in  
2 reaction to these shocks. A recent literature relies on natural experiments and on matched bank-  
3 firm-loan level data to precisely identify supply effects, although often at the cost of focusing on  
4 a single (emerging) country.<sup>19</sup> The fact that our results are very robust to accounting for all  
5 observable bank characteristics, however, is reassuring. Second, we saw that the BANKSCOPE  
6 data does not allow us to measure banks' domestic exposure in a precise manner. Our analysis  
7 of Section 2.2, however, indicates that the BANKSCOPE measure is a very good proxy for cross-  
8 bank variation in domestic exposure, at least for two recent and important episodes of  
9 heightened sovereign risk (the EU during 2010-2012, and Argentina 1997-2004). Often,  
10 moreover, home bias tends to increase in times of crisis, in which case our bondholdings measure  
11 – and its association with lending, which is the main object of this section – should be most  
12 accurate precisely during default episodes.<sup>20</sup>

13 But what determines a bank's bondholdings in the first place? This question speaks to: (i)  
14 the origins of the "dangerous embrace" of banks and governments, and to; (ii) the endogeneity  
15 of bondholdings to bank characteristics and country shocks. We now address this question.

16 *3.2. Determinants of Banks' Bondholdings*

---

<sup>19</sup> See, e.g., Khwaja and Mian (2008) on Pakistan, Paravisini (2008) on Argentina, Schnabl (2012) on Peru, Jimenez, Ongena, Peydro, and Saurina (2012) on Spain, Amiti and Weinstein (2012) on Japan, Paravisini, Rappoport, Schnabl, and Wolfenzon (2014) on Peru, Iyer, Lopes, Peydro and Schoar (2014) on Portugal.

<sup>20</sup> For evidence of increases in home bias during crises, see Broner, Didier, Erce, and Schmukler (2013).

1 Let  $B_{i,c,t}$  denote the ratio of government bonds over assets held in year  $t$ , by bank  $i$  located in  
 2 country  $c$ . We think of  $B_{i,c,t}$  as being chosen by bank  $i$  at  $t-1$  and, to study its determinants, we  
 3 run the following regression:

$$4 \quad B_{i,c,t} = \alpha_0 + \alpha_1 \cdot X_{i,c,t-1} + \alpha_2 \cdot X_{c,t-1} + \alpha_3 \cdot Def_{c,t-1} + \alpha_4 \cdot Def_{c,t-1} \cdot X_{i,c,t-1} + \\ 5 \quad + \alpha_5 \cdot Def_{c,t-1} \cdot X_{c,t-1} + \epsilon_{i,c,t}, \quad (5)$$

6 where  $Def_{c,t-1}$  is our default dummy. We estimate (4) in specifications that include country  
 7 dummies, time dummies, and their interaction. Standard errors are clustered at the bank level.

8 Vector  $X_{i,c,t-1}$  includes bank characteristics that may affect the demand for bonds, such  
 9 as loans outstanding (which proxies for a bank's investment opportunities), non-cash assets,

10 exposure to central bank, interbank balances, profitability, size, and whether or not the bank is  
 11 owned by the government. Lagged bondholdings are also included to control for persistence.

12 Vector  $X_{c,t-1}$  includes country-level factors such as financial development (as measured by  
 13 Private Credit to GDP and banking crises), GDP growth, inflation, and exchange rate depreciation.

14 We also control for the expected return of domestic bonds  $R_{c,t}^e$ , which captures the expectation  
 15 (at time  $t-1$ ) of the time- $t$  return of government bonds of country  $c$ . As explained in Section 2,  
 16 we fit this variable by using GMM to regress realized returns on country-specific risk factors.

17 Coefficients  $\alpha_1$  and  $\alpha_2$ , respectively, capture the effect of bank- and country-factors on a  
 18 bank's holdings of government bonds outside of default episodes (i.e., in "normal times").

19 Coefficients  $\alpha_3$ ,  $\alpha_4$  and  $\alpha_5$  capture the change in the demand for bonds during default episodes,  
 20 allowing such change to be heterogeneous across banks and countries. Equation (4) allows us to

1 test whether bondholdings behave differently in years of default relative to all other years. If  
2  $\alpha_3 > 0$ , for instance, all banks tend to increase their bondholdings during default events.

3 Table VIII reports the estimates of different specifications of Equation (4). Column (1)  
4 includes only time dummies. The demand for bonds in normal times exhibits two features. First,  
5 it is decreasing in outstanding loans, presumably because banks with more investment  
6 opportunities do not need to store their funds in public bonds. Second, bondholdings are also  
7 lower in more financially developed countries (i.e. those sustaining a high Private Credit/GDP  
8 ratio and not experiencing a banking crisis). Larger banks seem to hold more bonds in normal  
9 times, but this result is not robust across specifications.

10 Consider next how the patterns of bondholdings change during default events. This is  
11 captured by the coefficients of the default dummy, both alone and interacted with bank and  
12 country characteristics. The default dummy is insignificant, and it is bank- and country-  
13 characteristics that determine which banks purchase bonds during crises. The interaction  
14 between bank size and the default dummy suggests that large banks disproportionately  
15 accumulate government bonds during default. In fact, it is the concentration of bonds into large  
16 banks that accounts for the slight increase in bondholdings that is observed in our sample during  
17 defaults. Finally, the increase in bonds during default years is more pronounced in countries with  
18 more developed financial sector, as proxied by a high Private Credit/GDP ratio.

19 **[Table VIII here]**

1        These estimates may be contaminated by country level omitted factors, such as the  
2    supply of government bonds by the local government.<sup>21</sup> In Column (2) we thus introduce country  
3    dummies. We also include expected returns, which is an interesting variable to consider even  
4    though it reduces our sample size. Our main findings on the demand for bonds during sovereign  
5    default are confirmed. The fact that banks with fewer outstanding loans do not increase their  
6    bondholdings during default years suggests that, at these times, public bonds do not end up being  
7    concentrated in “bad” banks, which further reinforces the supply hypothesis.

8        Finally, Column (3) includes in our regression the interaction between country and time  
9    dummies to control for any country-specific shock. The main findings remain robust.

10       Overall, this section indicates that banks demand a sizeable amount of government bonds  
11    in normal times, particularly banks that have few investment opportunities and that operate in  
12    less financially developed countries. These results lend support to theories in which government  
13    bonds are held by banks in the regular course of their business activity, perhaps because they are  
14    good stores of value (e.g., Gennaioli et al. (2014)) or because they can be used as collateral in  
15    repo agreements (e.g., Bolton and Jeanne (2011)).

16       In line with recent work on Europe, banks in our sample also appear to accumulate some  
17    bonds during sovereign defaults. In our data, though, this effect is quite small (about 3% of banks'  
18    assets on average) and it occurs mostly in large banks, which happen to be more profitable. Thus,

---

<sup>21</sup> It could be, for instance, that governments in poorer and less financially-developed countries have higher debt levels for reasons that have nothing to do with the demand of bonds by banks. The inclusion of country dummies and country\*time dummies allows us to mitigate these and other omitted variables concerns.

1 our data do not support the notion that “bad” banks self-select themselves into buying bonds, as  
2 it seems to have been the case in the recent European crisis.<sup>22</sup>

3 The caveat here is that our data does not precisely measure holdings of domestic bonds.  
4 Hence, the increase in bondholdings during default years need not reflect greater domestic  
5 exposure. It is possible that, at such times, banks are actually purchasing foreign bonds. As we  
6 saw in Section 2.2, however, our data are quite informative about cross-bank variation in  
7 exposure to domestic government bonds. In this sense, although imperfect, our findings are likely  
8 to provide an accurate description of banks’ heterogenous exposures to their government.

#### 9 **4 Concluding Remarks**

10 We use a large bank-level sample containing 20 default episodes in 17 countries between 1998  
11 and 2012 to document two robust facts. First, there is a strong negative correlation between a  
12 bank’s holdings of government bonds and its lending during sovereign defaults. Second,  
13 bondholdings are large during normal times, particularly for banks that make fewer loans and are  
14 located in financially undeveloped countries.

15 Our findings are consistent with theories of imperfect creditor discrimination (e.g. Broner  
16 et al. (2010)) and in particular with theories in which sovereign defaults damage domestic banks  
17 (Gennaioli et al. (2014)). They indicate, moreover, that the sovereign default-banking crisis nexus  
18 is a feature of many countries around the world. Standard theories, in which the costs of default  
19 are only external, are thus bound to underestimate governments’ incentives to repay their debts.

---

<sup>22</sup> See Acharya and Steffen (2014) and Brutti and Saure (2013) for evidence in this regard.

1       Despite these similarities, our results also point to important differences between  
2 emerging and developed economies. The post-default decrease in bank lending appears to be  
3 stronger in countries with middle (as opposed to low) levels of economic and financial  
4 development, where financial intermediation plays an important role. There is little we can say  
5 about highly developed economies, since they simply do not default often enough in our sample.

6           But a more general comparison between more- and less-developed economies shows  
7 that banks in emerging economies hold a large amount of bonds in normal times (12.7% of assets  
8 in non-OECD countries). It is only natural to expect that these “normal-times” holdings should  
9 account for the bulk of the adverse effects of sovereign defaults on bank lending. In developed  
10 economies, by contrast, banks hold fewer bonds in normal times (5% of assets in OECD countries)  
11 and their take-up of bonds during crises is more important in relative terms. This difference may  
12 have significant implications for bank regulation. When setting the risk-weights of government  
13 bonds, for instance, authorities should take into account that they can be an important part of  
14 banks’ portfolios in normal times. More generally, regulatory efforts to curb banks’ holdings of  
15 public bonds may impose sizeable costs without adding much in terms of improved incentives,  
16 particularly in countries where banks rely heavily on the liquidity services of public debt.

**Table I – Bank's Holdings of Government Bonds from BANKSCOPE and Other Sources**

The table reports summary statistics of bank bondholdings as a percentage of total assets for selected samples.

Sample	EU Banks		GIIPS Banks		Argentine Banks	
Source	BANKSCOPE	Stress Test	BANKSCOPE	Stress Test	BANKSCOPE	Central Bank
Mean	8.16	5.12	9.43	6.22	14.23	11.34
Median	7.68	4.44	8.22	5.64	10.73	8.09
Correlation	0.69		0.76		0.77	
Sample Period	2010-2012		2010-2012		1997-2004	
No Obs.	126		65		589	
No Banks	66		33		142	

**Table II – Descriptive Statistics**

The table reports summary statistics of the main variables. Panel A reports summary statistics of the banks' holdings of government bonds, computed as a percentage of total assets. \*\*\* indicates significance at the 1% level; \*\* indicates significance at the 5% level; \* indicates significance at the 10% level. Panel B reports statistics on the BANKSCOPE universe and Panel C on banks involved in the EU stress test of 2010. Assets is the total book value in million \$ of the assets side of the bank's balance sheet; non-cash assets is total assets minus cash and due from banks, divided by total assets; leverage is one minus book value of equity (issued share capital plus other shareholders fund) divided by total assets; loans is total loans outstanding divided by total assets; profitability is operating income divided by total assets; exposure to central bank is total exposure to central bank divided by total assets; interbank balances is interest-earning balances with central and other banks divided by total assets; government owned is a dummy that equals one if the government owns more than 50% of the bank's equity. For details on the construction of all variables see Table AI in the online appendix.

**Table III – Bondholdings, Sovereign Default, and Changes in Loans**

The table presents coefficient estimates from pooled OLS regressions. The dependent variable changes in loans is computed as loans outstanding divided by total assets in year t minus loans outstanding divided by total assets in year t-1. The main independent variables are bank bondholdings, computed as bondholdings divided by total assets, and an indicator for sovereign default. Standard errors (in parentheses below the coefficient estimates) are adjusted for heteroscedasticity using the Huber (1967) and White (1980) correction, as well as clustering at the bank level using the Huber (1967) correction. \*\*\* indicates significance at the 1% level; \*\* indicates significance at the 5% level; \* indicates significance at the 10% level.

**Table IV – Bondholdings, Country Shocks, and Changes in Loans**

The table presents coefficient estimates from pooled OLS regressions. The dependent variable changes in loans is computed as loans outstanding in year  $t$  minus loans outstanding in year  $t-1$ , divided by total assets. The main independent variables are bank bondholdings, computed as bondholdings divided by total assets, an indicator for sovereign default, GDP annual percent growth, and exchange rate devaluation, computed as percent change in the exchange rate with the US dollar. Standard errors (in parentheses below the coefficient estimates) are adjusted for heteroscedasticity using the Huber (1967) and White (1980) correction, as well as for clustering at the bank level using the Huber (1967) correction. \*\*\* indicates significance at the 1% level; \*\* indicates significance at the 5% level; \* indicates significance at the 10% level.

**Table V – Bondholdings, Sovereign Default, and Changes in Loans: Robustness Tests**

The table presents coefficient estimates from pooled OLS regressions. The dependent variable changes in loans is computed as loans outstanding in year  $t$  minus loans outstanding in year  $t-1$ , divided by total assets. The main independent variables are bank average non-default years bondholdings, computed as the average of bank bondholdings in all the non-default years prior to and including year  $t-1$ , bank time-varying bondholdings, computed as bank bondholdings minus bank average non-default years bondholdings. Largest defaults are Argentina's, Russia's Ukraine's and Greece's. Standard errors (in parentheses below the coefficient estimates) are adjusted for heteroscedasticity using the Huber (1967) and White (1980) correction, as well as for clustering at the bank level using the Huber (1967) correction. \*\*\* indicates significance at the 1% level; \*\* indicates significance at the 5% level; \* indicates significance at the 10% level.

	Exclude government owned banks		Largest defaults only		No defaults with <5 banks		No defaults with <10 banks		No defaults with <15 banks		Haircut measure of default		Spread or Default measure of default

**Table VI – Bondholdings, Sovereign Default, and Changes in Loans: Cross-Country Variation**

The table presents coefficient estimates of the main independent variable from pooled OLS regressions. The dependent variable changes in loans is computed as loans outstanding divided by total assets in year t minus loans outstanding divided by total assets in year t-1. The main independent variables are bank bondholdings, computed as bondholdings divided by total assets, and an indicator for sovereign default. The other independent variable are loans divided by assets, and the interaction of sovereign default and loans. Regression specifications include also year and country fixed effects. Standard errors (in parentheses below the coefficient estimates) are adjusted for heteroscedasticity using the Huber (1967) and White (1980) correction, as well as for clustering at the bank level using the Huber (1967) correction. \*\*\* indicates significance at the 1% level; \*\* indicates significance at the 5% level; \* indicates significance at the 10% level. N/A indicates no default observations for the corresponding group of countries. Exchange rate policy data use the Shambaugh (2004) definitions of peg and soft peg. GDP per capita is obtained from the World Development Indicator; High corresponds to an average annual income above \$35K (measured in 2010 USD), Medium to an average annual income between \$7K and \$35K, and Low to an average annual income below \$7K. Creditor Rights is the score of Djankov et al (2007), where High is a score above 2, Medium is a score of 2, and Low is a score below 2. Economic Institutions is the economic score from ICRG (2013): High is a score above 40, Medium is a score between 35 and 40, Low is a score below 35. Political Institutions is the political score from ICRG (2013): High is a score above 80, Medium is a score between 65 and 80, Low is a score below 65.

**Table VII – Bondholdings and Changes in Loans: Normal Times v Default Years Bonds**

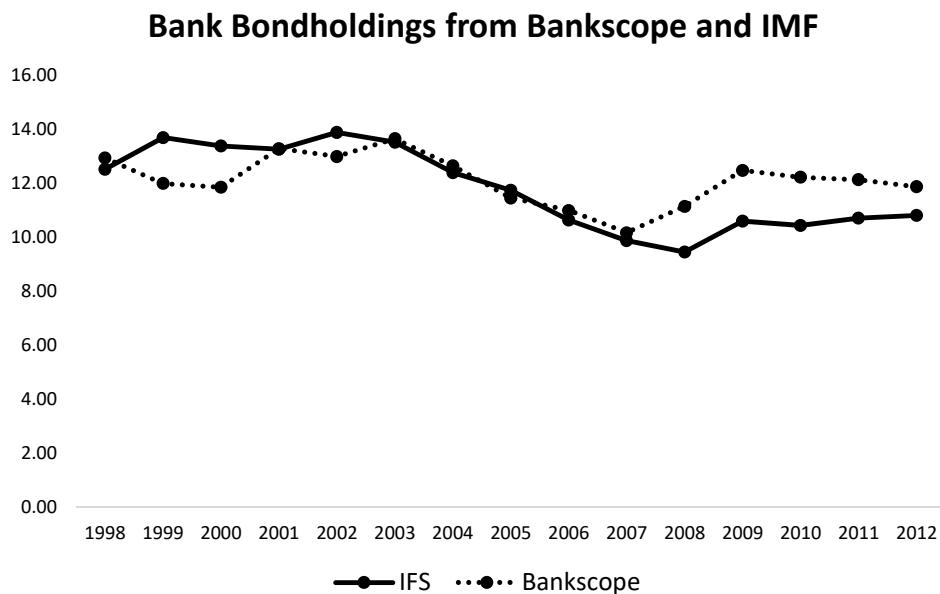

The table presents coefficient estimates from pooled OLS regressions. The dependent variable changes in loans is computed as loans outstanding in year t minus loans outstanding in year t-1, divided by total assets. The main independent variables are pre-default bank bondholdings, computed as bondholdings in the year prior to the first year of a sovereign default, divided by total assets; average pre-default bank bondholdings, computed as the average of bondholdings divided by total assets in the last three years prior to the first year of a sovereign default. Standard errors (in parentheses below the coefficient estimates) are adjusted for heteroscedasticity using the Huber (1967) and White (1980) correction, as well as for clustering at the bank level using the Huber (1967) correction. \*\*\* indicates significance at the 1% level; \*\* indicates significance at the 5% level; \* indicates significance at the 10% level.

**Table VIII – Banks' Demand for Government Bonds**

The table presents coefficient estimates from pooled OLS regressions. The dependent variable is bank bondholdings, and it is computed as bondholdings divided by total assets. Size is the natural logarithm of total assets; non-cash assets is total assets minus cash and due from banks, divided by total assets; leverage is one minus book value of equity (issued share capital plus other shareholders fund) divided by total assets; loans is total loans outstanding divided by total assets; profitability is operating income divided by total assets; exposure to central bank is total exposure to central bank divided by total assets; interbank balances is interest-earning balances with central and other banks divided by total assets; government owned is a dummy that equals one if the government owns more than 50% of the bank's equity. Sovereign default is a binary variable that equals 1 if the sovereign is in default in year  $t-1$  and 0 otherwise; GDP growth is natural logarithm of GDP in year  $t$  minus natural logarithm of GDP in year  $t-1$ ; aggregate leverage is the country-year average of bank leverage; banking crisis is a binary variable that equals 1 if the country is in a banking crisis in year  $t-1$  and 0 otherwise; private credit is the ratio of credit from deposit taking financial institutions to the private sector to GDP, expressed as a percentage; exchange rate devaluation is the percent change in the exchange rate with the US dollar. Standard errors (in parentheses below the coefficient estimates) are adjusted for heteroscedasticity using the Huber (1967) and White (1980) correction, as well as for clustering at the bank level using the Huber (1967) correction. \*\*\* indicates significance at the 1% level; \*\* indicates significance at the 5% level; \* indicates significance at the 10% level.

**Figure 1. Bank Bondholdings from BANKSCOPE and IMF.** The figure plots bank bondholdings over 1998-2012 for all country-years covered by both BANKSCOPE and the IMF.

**Figure 2. Sovereign Bond Prices in Defaulting Countries.** The figure plots the average bond prices over 7 default episodes in 6 countries (Argentina 2001-2004, Russia 1998-2000, Cote d'Ivoire 2000-2004, Ecuador 1998-2000, Ecuador 2009, Nigeria 2002, Greece 2012), from day -1,000 to +1,000, whereby day 0 is the day in which default is announced.
